Query Processing 7.1

• Diese Vorlesung basiert auf dem Kurs

Architecture and Implementation of Database Systems von Jens Teubner, ETH Zürich

 Ich bedanke mich f
ür die Bereitstellung des Materials

A DBMS needs to do a number of tasks

- with limited memory resources,
- over large amounts of data,
- yet as fast as possible.

Query Processing

Sorting

Sorting is a core database operation with numerous applications:

• A SQL query may explicitly request **sorted output**:

SELECT A, B, C FROM R ORDER BY A

- ▶ Bulk-loading a B⁺-tree presupposes sorted data.
- Duplicate elimination is particularly easy over sorted input:

SELECT DISTINCT A, B, C FROM R

 Some database operators rely on their input files being already sorted (some of which meet later in this course).

How can we sort a file that exceeds the available main memory size by far (let alone the available buffer manager space)?

Two-Way Merge Sort

We start with **two-way merge sort**, which can sort files of arbitrary size with only **three pages** of buffer space.

Two-way merge sort sorts a file with $N = 2^k$ pages in multiple **passes**, each of them producing a certain number of sorted sub-files called **runs**.

- Pass o sorts each of the 2^k input pages individually and in main memory, resulting in 2^k sorted runs.
- Subsequent passes merge pairs of runs into larger runs. Pass n produces 2^{k-n} runs.
- **Pass** *k* leaves only one run left, the sorted overall result.

During each pass, we read every page in the file. Hence, $(k + 1) \cdot N$ page reads and $(k + 1) \cdot N$ page writes are required to sort the file.

Pass 1

Pass o (Input: $N = 2^k$ unsorted pages; Output: 2^k sorted runs)

- 1. Read *N* pages, one page at a time
- 2. Sort records in main memory.
- 3. Write sorted pages to disk (each page results in a run).

This pass requires **one page** of buffer space.

(Input: $N = 2^k$ sorted runs; Output: 2^{k-1} sorted runs)

- 1. Open two runs r_1 and r_2 from Pass o for reading.
- 2. **Merge** records from r_1 and r_2 , reading input page-by-page.
- 3. Write new two-page run to disk (page-by-page).

This pass requires three pages of buffer space.

Pass n (Input: 2^{k-n+1} sorted runs; Output: 2^{k-n} sorted runs)
1. Open two runs r₁ and r₂ from Pass n - 1 for reading.
2. Merge records from r₁ and r₂, reading input page-by-page.
3. Write new 2ⁿ-page run to disk (page-by-page).
This pass requires three pages of buffer space.

Illustration / Example

Fall 2008

Two-Way Merge Sort: I/O Behavior

- To sort a file of N pages, we need to read and write N pages during each pass
 - \rightarrow 2 · *N* I/O operations per pass.

• The number of passes is
$$\underbrace{1}_{Pass o} + \underbrace{[log_2 N]}_{Passes 1...k}$$

Total number of I/O operations:

$$2 \cdot N \cdot (1 + \lceil \log_2 N \rceil)$$

How many I/Os does it take to sort an 8 GB file?

Sequential vs. Random Access

Example: Read 1000 blocks of size 8 KB

random access:

 $t_{\rm rnd} = 1000 \cdot 14.33 \,{\rm ms} = 14.33 \,{\rm s}$

sequential read:

 $t_{seq} = t_s + t_r + 1000 \cdot t_{tr} + \frac{16 \cdot 1000}{63} \cdot t_{s,track-to-track}$ = 10 ms + 4.14 ms + 160 ms + 254 ms \approx 428 ms

The Travelstar 7K200 has 63 sectors per track, with a 1 ms track-to-track seek time; one 8 KB block occupies 16 sectors.

- \rightarrow Sequential I/O is **much** faster than random I/O.
- \rightarrow Avoid random I/O whenever possible.
- $\rightarrow\,$ As soon as we need at least $\frac{428\,\text{ms}}{14330\,\text{ms}}=3\,\%$ of a file, we better read the **entire** file!

External Merge Sort

So far we "voluntarily" used only three pages of buffer space.

How could we make effective use of a significantly larger buffer pool (of, say, *B* memory frames)?

There are basically two knobs we can turn:

- Reduce the number of initial runs by using the full buffer space during the in-memory sort.
- Reduce the number of passes by merging more than 2 runs at a time.

Reducing the Number of Initial Runs

With *B* frames available in the buffer pool, we can read *B* pages at a time during Pass o and sort them in memory (\nearrow slide 122):

Pass 0 (Input: N unsorted pages; Output: [N/B] sorted runs)
1. Read N pages, B pages at a time
2. Sort records in main memory.
3. Write sorted pages to disk (resulting in [N/B] runs).

This pass uses *B* pages of buffer space.

The number of initial runs determines the number of passes we need to make (\nearrow slide 124):

 \rightarrow Total number of I/O operations: $2 \cdot N \cdot (1 + \lceil \log_2 \lceil N/B \rceil \rceil)$.

How many I/Os does it now take to sort an 8 GB file?

Reducing the Number of Passes

With *B* frames available in the buffer pool, we can **merge** B - 1 pages at a time (leaving one frame as a write buffer).

Pass *n* (Input: $\frac{\lceil N/B \rceil}{(B-1)^{n-1}}$ sorted runs; Output: $\frac{\lceil N/B \rceil}{(B-1)^n}$ sorted runs) 1. Open $\underline{B} - 1$ runs $\underline{r_1 \dots r_{B=1}}$ from Pass n - 1 for reading. 2. Merge records from $\underline{r_1 \dots r_{B=1}}$, reading input page-by-page. 3. Write new $\underline{B} \cdot (\underline{B} - 1)^n$ -page run to disk (page-by-page). This pass requires B pages of buffer space.

With *B* pages of buffer space, we can do a (B - 1)-way merge.

 \rightarrow Total number of I/O operations: $2 \cdot N \cdot (1 + \lceil \log_{B-1} \lceil N/B \rceil \rceil)$.

How many I/Os does it now take to sort an 8 GB file?

a1:

External Sorting: I/O Behavior

Sorting N pages with B buffer frames requires

$$2 \cdot N \cdot (1 + \lceil \log_{B-1} \lceil N/B \rceil])$$

I/O operations.

Solution What is the access pattern of these I/Os?

Blocked I/O

We could improve the I/O pattern by reading **blocks** of, say, *b* pages at once during the **merge** phases.

- Allocate b pages for each input (instead of just one).
- ▶ Reduces per-page I/O cost by a factor of ≈ *b*.
- The price we pay is a decreased fan-in (resulting in an increased number of passes and more I/O operations).
- In practice, main memory sizes are typically large enough to sort files with just one merge pass, even with blocked I/O.

How long does it take to sort 8 GB (counting only I/O cost)? 1000 buffer pages, 8 KB each; 10 ms total disk latency

- ▶ Without blocked I/O: $\approx 4 \cdot 10^6$ disk seeks (11.6 h) + transfer of $\approx 6 \cdot 10^6$ disk pages (17 min)
- ▶ With blocked I/O (32 page blocks): $\approx 6 \cdot 32,768$ disk seeks (33 min) + transfer of $\approx 8 \cdot 10^6$ disk pages (22 min)

Selection Trees

71

Choosing the next record from B - 1 (or B/b - 1) input runs can be quite CPU intensive (B - 2 comparisons).

- Use a selection tree to reduce this cost.
- ► E.g., "tree of losers" (/ D. Knuth, TAoCP, vol. 3):

• This cuts the number of comparisons to $\log_2 (B - 1)$.

External Sorting—Discussion

• External sorting follows the principle of **divide and conquer**.

- This leads to a number of independent tasks.
- These tasks can be executed in parallel (think of multi-processor machines or distributed databases).
- External sorting makes sorting very efficient. In most practical cases, two passes suffice to sort even huge files.
- There are a number of tweaks to tune sorting even further:
 - Replacement sort: Re-load new pages while writing out initial runs in Pass o, thus increasing the initial run length.
 - Double buffering: Interleave page loading and input processing in order to hide disk latency.

FI

Query Plans

Actual DB2 execution plan.

- External sorting is one instance of a (physical) database operator.
- Operators can be assembled into a query execution plan.
- Each plan operator performs one sub-task of a given query. Together, the operators of a plan evaluate the full query.
- We'll have a deeper look into join operators next.

71

The **join operator** \bowtie_p is actually a short-hand for a combination of **cross product** \times and **selection** σ_p .

One way to implement \bowtie_p is to follow this equivalence:

- 1. Enumerate all records in the cross product of *R* and *S*.
- 2. Then pick those that satisfy *p*.

More advanced algorithms try to avoid the obvious inefficiency in Step 1 (the size of the intermediate result is $|R| \cdot |S|$).

Nested Loops Join

The **nested loops join** is the straightforward implementation of the σ -× combination:

1 Function: nljoin (R, S, p) **2 foreach** record $r \in R$ **do 3 foreach** record $s \in S$ **do 4 if** $\langle r, s \rangle$ satisfies p **then 5 b c append** $\langle r, s \rangle$ to result

Let N_R and N_S the number of **pages** in *R* and *S*; let p_R and p_S be the number of records per page in *R* and *S*.

The total number of disk reads is then

$$N_R + \underbrace{p_R \cdot N_R}_{\# \text{ tuples in } R} \cdot N_S$$
.

Nested Loops Join: I/O Behavior

The **good news** about nljoin () is that it needs only **three pages** of buffer space (two to read *R* and *S*, one to write the result).

The **bad news** is its enormous I/O cost:

- ► Assuming $p_R = p_S = 100$, $N_R = 1000$, $N_S = 500$, we need to read $1000 + (5 \cdot 10^7)$ disk pages.
- With an access time of 10 ms for each page, this join would take 140 hours!
- Switching the role of R and S to make S (the smaller one) the outer relation does not bring any significant advantage.

Note that reading data page-by-page (even tuple-by-tuple) means that **every** I/O suffers the disk latency penalty, even though we process both relations in sequential order.

Block Nested Loops Join

Again we can save random access cost by reading R and S in **blocks** of, say, b_R and b_S pages.

- 1 Function: block_nljoin (R, S, p)
- ² **foreach** b_R -sized block in R **do**
- \mathbf{s} foreach b_{s} -sized block in S do
- 4 find matches in current *R* and *S*-blocks and append them to the result ;

- ▶ *R* is still read once, but now with only $\lceil N_R/b_R \rceil$ disk seeks.
- ► *S* is scanned only $\lceil N_R/b_R \rceil$ times now, and we need to perform $\lceil N_R/b_R \rceil \cdot \lceil N_S/b_S \rceil$ disk seeks to do this.

Choosing b_R and b_S

E.g., buffer pool with B = 100 frames, $N_R = 1000$, $N_S = 500$:

Fall 2008

In-Memory Join Performance

- Line 4 in block_nljoin (R, S, p) implies an in-memory join between the R- and S-blocks currently in memory.
- Building a hash table over the *R*-block can speed up this join considerably.
- 1 Function: block_nljoin' (R, S, p)
- ² foreach b_R -sized block in R do
 - build an in-memory hash table *H* for the current *R*-block ;
 foreach b_S-sized block in *S* do
 - foreach record s in current S-block do
 - probe *H* and append matching $\langle r, s \rangle$ tuples to result ;

Note that this optimization only helps equi-joins.

3

4

5

6

71

Index Nested Loops Join

The **index nested loops join** takes advantage of an index on the **inner** relation (swap *outer* \leftrightarrow *inner* if necessary):

- 1 Function: index_nljoin (R, S, p)
- ² foreach record $r \in R$ do
- probe index using r and append all matching tuples to result;
- ► The index must be compatible with the join condition *p*.
 - ► Hash indices, *e.g.*, only support equality predicates.
 - Remember the discussion about composite keys in B^+ -trees (\nearrow slide 73).

I/O Behavior

71

For each record in *R*, we use the index to find matching *S*-tuples. While searching for matching *S*-tuples, we incur the following I/O costs **for each tuple** in *R*:

- 1. Access the index to find its first matching entry: N_{idx} I/Os.
- 2. **Scan** the index to retrieve **all** *n* matching *rids*. The I/O cost for this is typically negligible.
- 3. **Fetch** the *n* matching *S*-tuples from their data pages.
 - ▶ For an **unclustered** index, this requires *n* I/Os.
 - For a **clustered** index, this only requires $\lceil n/p_s \rceil$ I/Os.

Note that (due to 2 and 3), the cost of an index nested loops join becomes dependent on the size of the join **result**.

71

If the index is a **B⁺-tree index**:

- ► A **single** index access requires the inspection of *h* pages.⁹
- If we repeatedly probe the index, however, most of these are cached by the buffer manager.
- The effective value for N_{idx} is around 1–3 I/Os.
- If the index is a **hash index**:
 - Caching doesn't help us here (no locality in accesses to hash table).
 - A typical value for N_{idx} is 1.2 I/Os (due to overflow pages).

Overall, the use of an index (over, *e.g.*, a block nested loops join) pays off if the join picks out only few tuples from a big table.

⁹h: B⁺-tree height

Sort-Merge Join

FI

Join computation becomes particularly simple if both inputs are **sorted** with respect to the join attribute(s).

- The merge join essentially merges both input tables, much like we did for sorting.
- Contrast to sorting, however, we need to be careful whenever a tuple has **multiple** matches in the other relation:

Δ	R			
,,	0		C	D
"foo"	1	B=C	-	falsa
"foo"	h		1	laise
100	2		C	true
"bar"	2		2	tiuc
	-		2	false
"baz"	2		~	+
"bof"	Λ		3	true
Dai	4			

• Merge join is typically used for **equi-joins only**.

```
FI
 1 Function: merge_join (R, S, \alpha = \beta)
                                                       // \alpha, \beta: join columns in R, S
 2 r \leftarrow \text{position of first tuple in } R;
 3 s \leftarrow \text{position of first tuple in } S;
4 while r \neq eof and s \neq eof do
        while r.\alpha < s.\beta do
 5
             advance r;
 6
        while r.\alpha > s.\beta do
 7
             advance s;
 8
        s' \leftarrow s:
                                              // Remember current position in S
9
        while r.\alpha = s'.\beta do
                                               // All R-tuples with same \alpha value
10
             s \leftarrow s':
11
                                               // All S-tuples with same \beta value
             while r.\alpha = s.\beta do
12
                  append \langle r, s \rangle to result;
13
                  advance s :
14
```

advance r;

```
// r. s. s': cursors over R. S. S
```

```
// eof: end of file marker
```

// Rewind s to s'

Fall 2008

15

I/O Behavior

71

- If both inputs are already sorted **and** there are no exceptionally long sequences of identical key values, the I/O cost of a merge join is N_R + N_S (which is optimal).
- By using blocked I/O, these I/O operations can be done almost entirely as sequential reads.
- Sometimes, it pays off to explicitly sort a (unsorted) relation first, then apply merge join. This is particularly the case if a sorted output is beneficial later in the execution plan.
- The final sort pass can also be combined with merge join, avoiding one round-trip to disk and back.

What is the worst-case behavior of merge join?

If both join attributes are constants and carry the same value (*i.e.*, the result is the Cartesian product), merge join degenerates into a nested loops join.

Hash Join

71

- Sorting effectively brought related tuples into spacial proximity, which we exploited in the merge join algorithm.
- We can achieve a similar effect with hashing, too.
- ▶ Partition R and S into partitions R₁,..., R_n and S₁,..., S_n using the same hash function (applied to the join attributes).

• Observe that $R_i \bowtie S_i = \emptyset$ for all $i \neq j$.

Hash Join

FI

- By partitioning the data, we reduced the problem of joining to smaller sub-relations R_i and S_i.
- Matching tuples are guaranteed to end up together in the same partition.
- We only need to compute $R_i \bowtie S_i$ (for all *i*).
- ► By choosing *n* properly (*i.e.*, the hash function *h*), partitions become small enough to implement the *R_i* ⋈ *S_i* as in-memory joins.

Use a different hash function h' for the in-memory join. [™] Why?

Hash Join Algorithm

71

- 1 Function: hash_join (R, S, lpha=eta)
- ² foreach record $r \in R$ do
- append *r* to partition $R_{h(r,\alpha)}$
- **4 foreach** record $s \in S$ **do**

s append s to partition $S_{h(s,\beta)}$

- 6 foreach partition $i \in 1, \ldots, n$ do
 - build hash table *H* for R_i , using hash function h';
 - **foreach** block in *S_i* **do**

foreach record *s* in current *S_i*-block **do**

probe *H* and append matching tuples to result ;

7

8

9

10

Hash Join—Buffer Requirements

- ► We've assumed that we can create the necessary n partitions in one pass (note that we want N_{R_i} < (B − 1)).</p>
- This works out if *R* consists of **at most** $\approx (B 1)^2$ pages.

Solution Why $(B-1)^2$? Why \approx ?

- ► We can write out at most B 1 runs in one pass; each of them should be at most B — 1 pages in size.
- ▶ Hashing doesn't guarantee us an even distribution. Since the actual size of each run varies, *R* must actually be smaller than $(B 1)^2$.
- ► Larger input tables require **multiple passes** for partitioning.

a1:

Hash Join vs. Sort-Merge Join

Provided sufficient buffer space ($B \gtrsim \sqrt{N}$), hash join and sort-merge join **both** require 3 ($N_R + N_S$) I/Os.¹⁰

► For sort-merge join, both relations need to be smaller than B(B-1) (assuming we need to sort before the join), *i.e.*,

 $N_R < B(B-1)$ and $N_S < B(B-1)$.

► In case of hash join, only the inner relation needs to be partitioned into (B - 1)-sized chunks, i.e.,

 $\min(N_R,N_S) \lesssim (B-1)^2$.

 The cost for hash join could considerably increase if partitions aren't uniformly sized.

¹⁰Read/write both relations to partition/sort; read both relations to join.

ati

Implementing Grouping and Duplicate Elimination

- Challenge is to find **identical tuples** in a file.
- This task has obvious similarities to a self-join based on all of the file's columns.
 - → Could use a **hash join-like** algorithm or **sorting** to implement duplicate elimination or grouping.
- See **exercises** for further details.

FI

Other Database Operators

Projection π

FI

- Text book-style processing of π implies
 - (a) discarding unwanted fields and
 - (b) eliminating duplicates.
- Implementing (a) amounts to a straightforward file scan.
 We have mentioned implementations for (b) a moment ago.
- Typically, systems try to avoid (b) whenever possible. In SQL, duplicate elimination has to be asked for explicitly.

Selection σ

- A straightforward approach to σ is a **file scan**.
- Alternatively, we can exploit sortedness or take advantage of an available index.

Orchestrating Operator Evaluation

So far we have assumed that all database operators consume and produce **files** (*i.e.*, on-disk items):

Obviously, this causes a lot of I/O.

In addition, we suffer from long response times:

- An operator cannot start computing its result before all its input files are fully generated ("materialized").
- Effectively, all operators are executed in sequence.

71

Pipelined Evaluation

FI

- Alternatively, each operator could pass its result directly on to the next operator (without persisting it to disk first).
- Don't wait until entire file is created, but propagate output immediately.
- Start computing results as early as possible, *i.e.*, as soon as enough input data is available to start producing output.
- This idea is referred to as pipelining.
- The granularity in which data is passed may influence performance:
 - Smaller chunks reduce the **response time** of the system.
 - Larger chunks may improve the effectiveness of (instruction) caches.
 - Actual systems typically operate **tuple at a time**.

Unix: Pipelines of Processes

Unix uses a similar mechanism to communicate between processes ("operators"):

Execution of this pipe is driven by the **rightmost** operand:

- To produce a line of output, cut only needs to see the next line of its input: grep is requested to produce this input.
- To produce a line of output, grep needs to request as many input lines from the xargs process until it receives a line containing the string "XML".
- ► ...
- Each line produced by the find process is passed through the pipe until it reaches the cut process and eventually is echoed to the terminal.

The Volcano Iterator Model

- The calling interface used in database execution runtimes is very similar to the one used in Unix process pipelines.
- In databases, this interface is referred to as open-next-close interface or Volcano iterator model.
- Each operator implements the functions
 - open () Initialize the operator's internal states.
 - **next** () Produce and return the **next result tuple**.
 - close () Clean up all allocated resources (typically after all tuples have been processed).
- All **state** is kept inside each operator.

✓ Goetz Graefe. Volcano—An Extensibel and Parallel Query Evaluation System. *Trans. Knowl. Data Eng.* vol. 6, no. 1, February 1994.

71

Example: Selection (σ **)**

- Input operator R, predicate p.
 - 1 Function: open ()
 - 2 R.open();
 - 1 Function: close ()
 - 2 R.close();
 - 1 Function: next ()
 - 2 while $((r \leftarrow R.next()) \neq eof)$ do 3 | if p(r) then 4 | return r;
 - 5 return eof;

Blocking Operators

71

- Pipelining reduces memory requirements and response time since each chunk of input is propagated to the output immediately.
- Some operators cannot be implemented in such a way.

Which ones?

- (external) sorting (this is also true for Unix sort)
- hash join
- grouping and duplicate elimination over unsorted input
- Such operators are said to be blocking.
- Blocking operators consume their entire input before they can produce any output.
 - The data is typically buffered ("materialized") on disk.

Techniques We Saw In This Chapter

Divide and Conquer

Many database algorithms derive their power from chopping a large input problem into smaller, manageable pieces, *e.g.*,

- run generation and merging in external sorting,
- partitioning according to a hash function (hash join).

Blocked I/O

FI

Reading and writing chunks of pages at a time can significantly reduce the degree of random disk access.

 \rightarrow This "trick" was applicable to most operators we saw.

Pipelined Processing

The Volcano iterator model can save memory and reduce response time by avoiding the full materialization of intermediate results if possible.
